## **Abstract**

We study the foundations for the development of contingent reasoning and the cognitive abilities that facilitate optimal behavior. Individuals from 11 to 17 years old participate in a simplified version of the deterministic “acquire-a-company” adverse selection game. We find that even our youngest subjects understand well the fundamentals of contingent reasoning (offer the reservation price of one of the sellers), although they do not necessarily choose the optimal price. Performance improves steadily and significantly over the developmental window but it is not facilitated by repeated exposure or feedback. High cognitive ability, measured by a high performance in a working memory task, is necessary to behave optimally in the simplest settings but it is not sufficient to solve the most complex situations.

**Keywords:** developmental decision-making, lab-in-the-field experiment, contingent reasoning, winner’s curse.

**JEL Classification:** C93, D82.

---

\* We thank the members of the Los Angeles Behavioral Economics Laboratory (LABEL) –in particular Sobhana Atluri, Sacha Bazzal, Matt Burr, Irfan Khan and Wen Lu– for their insights and research assistance, to Chris Crabbe for his outstanding programming skills, and to David Gill, Muriel Niederle, Matthias Sutter and Emanuel Vespa for helpful comments. We are grateful to the staff of the Lycée International de Los Angeles –in particular Emmanuelle Acker, Mathieu Mondange and Anneli Harvey– for their support in running the experiment in their school. The study was conducted with the University of Southern California IRB approval UP-12-00528. We acknowledge the financial support of the National Science Foundation grant SES-1851915.

# 1 Introduction

It has been extensively documented in the experimental literature that individuals have a difficult time making profit maximizing decisions in situations involving contingent reasoning. Examples include the winner’s curse in common value auctions ([Kagel and Levin, 1986](#)), zero-sum betting ([Sonsino et al., 2002](#)) and asset trading for informational reasons ([Carrillo and Palfrey, 2011](#)). Researchers have proposed behavioral theories to model the imperfect ability of subjects to understand the relationship between the actions and the information of other players ([Eyster and Rabin, 2005](#); [Crawford and Iribarri, 2007](#); [Esponda, 2008](#); [Rogers et al., 2009](#)) and studied lookup patterns to differentiate between choice mistakes and limited attention ([Brocas et al., 2014](#)).

One of the most elegant formalizations of contingent reasoning is the “acquire-a-company” game ([Samuelson and Bazerman, 1984](#)), where a buyer makes a take-it-or-leave-it offer to a seller for a company. The company’s value  $v$  is privately known to the seller and is worth a premium to the buyer. This model is analogous to a lemon’s problem ([Akerlof, 1970](#)) and, under some parameter assumptions, information asymmetry results in no exchange despite the potential welfare gains from trade. The experimental literature has shown that individuals have considerable difficulties in finding the optimal strategy ([Grosskopf et al., 2007](#); [Bereby-Meyer and Grosskopf, 2008](#)). Since the setting involves multiple players, beliefs about the behavior of others play a fundamental role in the buyer’s choice. Also, computing a conditional expectation requires some relatively challenging bayesian computations that are known to be difficult for many individuals. Overall, this literature has been successful in identifying some of the difficulties faced by participants. However, the complexity of the environment has been a handicap to achieve a full understanding of the reasons for the observed departures.

To further advance this comprehension, the experimental papers by [Charness and Levin \(2009\)](#) and [Martínez-Marquina et al. \(2019\)](#) (from now on [CL] and [MNV]) strip down the problem to its very essence. [CL] automatize the seller’s decision problem and restrict the company’s worth to only two possible values. The paper shows that even in this extremely simplified setting, 40% to 70% of subjects still deviate from the theoretical prediction.<sup>1</sup> [MNV] transform the probabilistic problem into a deterministic one by assuming that the buyer faces two companies, one of each value, but it is required to make the same offer to both. The authors show that equilibrium compliance improves under this formally equivalent presentation, thereby highlighting the “power of certainty.” Equilibrium play

---

<sup>1</sup>Deviations are still very significant when participants play in teams ([Casari et al., 2016](#); [Cooper and Sutter, 2018](#)) and the response is stronger to adverse selection than to advantageous selection ([Ali et al., 2019](#)).

increases further if buyers are educated first, by playing a number of trivial rounds against only one company of known value. However, and despite all these improvements, the proportion of individuals who play optimally remains low.

The goal of the present paper is to provide a foundational investigation of the development of contingent reasoning and the cognitive abilities that facilitate optimal behavior. To this purpose, we study the evolution of behavior in the acquire-a-company game from preadolescence to young adulthood (11 to 17 years old). The above mentioned research shows that contingent reasoning is difficult for educated adults. We want to determine if this skill takes time to acquire, is invariant to age or is lost during adolescence. We also want to find out which features make contingent thinking so complex. In particular, we are interested in studying at which age (if any) are individuals capable of learning from their mistakes. Finally, but importantly, we determine if the ability to perform well in this task is related to known cognitive abilities critical to complex reasoning.

We consider [MNV]’s version of [CL], and simplify it further in three dimensions. First, we present a graphical, story-based version. Limiting the analytical requirements ensures comprehension and helps retaining the interest of our youngest participants without affecting its essence. Second, we consider an additive instead of a multiplicative buyer’s premium ( $v + x$  with  $x > 0$  instead of  $\alpha v$  with  $\alpha > 1$ ), which further facilitates numerical calculations. Third, we provide feedback after each round (whether none, one or both companies are acquired and, if they are, the net payoff of each transaction). This allows us to study initial behavior as well as learning. At the end of the experiment, we ask participants to complete a working memory task to assess the contribution of cognition to optimal behavior in the game. Notice that by studying only the deterministic setting, we remove the “power of certainty” component (in the terminology of [MNV]) and retain only the most fundamental contingent reasoning aspect of the adverse selection problem, namely how a given offer affects the profit in each contingency.<sup>2</sup>

The reader may find it adventurous to study developmental decision-making in settings that are already difficult for educated adults. We should notice, however, that existing research using indirect (Harbaugh et al., 2001) as well as direct (Brocas et al., 2019) tests of transitivity has demonstrated that by the end of elementary school, children have achieved a level of rationality comparable to that of adults, at least in terms of GARP consistency and transitivity of preferences. This suggests that, by 10 years of age, many children are equipped with the cognitive tools necessary to understand this type of problems. The question we address is whether, at this young age, they are already able to transform this

---

<sup>2</sup>In the paper, we focus on this narrow definition of contingent reasoning in adverse selection. Needless to say, *any* game theoretic situation is subject to some type of contingent reasoning since the individual has to determine how his/her strategy affects and is affected by the strategy of others.

capacity into optimal behavior.

Our main findings are the following. First, the vast majority of our subjects—including the youngest ones—show a solid understanding of the fundamental principles of contingent reasoning. Indeed, 75% (6th grade) to 97% (10th grade) of participants in a grade offer “reasonable” prices in every round, namely, one of the seller’s values. No subject offers the average value of the two sellers. Second, the fraction of individuals who submit the optimal price in every round increases steadily and significantly with age in the entire window of observation, from 11% in 6-7th grade to 50% in 11th grade, and all the way to 70% in the control population. We conjecture that our simple narrative and graphical design may have contributed to an increased comprehension of the problem relative to the previous literature. Third, comprehension of the simple one-seller problem is predictive of optimal pricing in every age group. It suggests that a main challenge in problems involving contingent thinking is the difficulty to understand basic aspects of the problem, even more than the ability to maximize profits once these aspects are understood. Finally, performance in the working memory task highly correlates with the basic ability to realize which prices are potentially optimal (one of the sellers’ values) and, to a lesser extent, with the more subtle ability to optimally discriminate between the two. It suggests that working memory alone accounts for some but not all the variance in reasoning abilities. It also raises a more general question: is working memory a fundamental cognitive ability which is necessary for (and predictive of) contingent reasoning not only in children and adolescents but also in young and old adults? Our tentative answer would be “yes”, but future research in adults should explore this correlation in more depth.

## 2 Experimental design

The paper studies a graphical, simplified, deterministic version of the acquire-a-company game ([CL] and [MNV]) in a population of preadolescents and teenagers (11 to 18 years old). This pool of individuals presents some methodological challenges. We follow the guidelines proposed by [Brocas and Carrillo \(forthcoming\)](#) to address them.<sup>3</sup>

*Participants.* We recruited 261 participants (133 females) from 6th to 11th grade at the Lycée International de Los Angeles (LILA), a French-English bilingual private school in Los Angeles.<sup>4</sup> For comparison, we ran the same experiment with a control population

---

<sup>3</sup>The relevant principles for this experiment are: (i) simplify the procedures given the participants’ limited attention; (ii) offer age-appropriate incentives; (iii) present the task in a simple and attractive way; and (iv) include a benchmark adult comparison group.

<sup>4</sup>Students from 12th grade did not participate in the study because they were preparing for national french exams.

of 71 USC college undergraduates (U) using the same procedures. Table 1 reports the distribution of participants by grade and approximate age.<sup>5</sup>

Grade	LILA						USC U
	6th	7th	8th	9th	10th	11th	
Age	11-12	12-13	13-14	14-15	15-16	16-17	18-23
Participants	55	45	62	36	33	30	71

**Table 1:** Number of participants by grade

Studies with adolescents usually do not recruit an adult population. We believe it is important to include an adult control group to establish a behavioral benchmark, even if the comparison is imperfect. In our case, the majority of students at LILA are from caucasian families of upper-middle socioeconomic status. After graduation, most of them attend well-ranked colleges in Europe, Canada and the US (with a non-negligible fraction attending USC and schools in the UC system). Despite some differences (nationality, family background, size of peer group, etc.), the two populations match reasonably well. Also, while the pool is not representative of the US population, it is homogenous, making it possible to perform meaningful age comparisons. Indeed, as shown in previous research (Brocas and Carrillo, 2019), the strategic behavior of children is highly dependent on a variety of economic and demographic characteristics (see also Charness et al. (2019)). Pooling participants from different schools could introduce confounds that hide any developmental trajectory. We avoid these confounds by recruiting children from the same school, who follow the same curriculum, and come from similar social and economic backgrounds.<sup>6</sup> We also collect information about gender and number of siblings to capture potential remaining sources of individual heterogeneity. Finally, there is no self-selection within the school, as only 3 students in the entire school opted out of the study. The participation rate was 87% due to school absences and testing constraints on the days of the experiment.

*Procedures.* We ran 33 and 8 sessions at LILA and USC with 6 to 12 participants each. Sessions at LILA were run in classrooms during school hours with individual partitions to preserve anonymity. Sessions had a mix of male and female participants always from the same grade. Sessions at USC were run at the Los Angeles Behavioral Economics

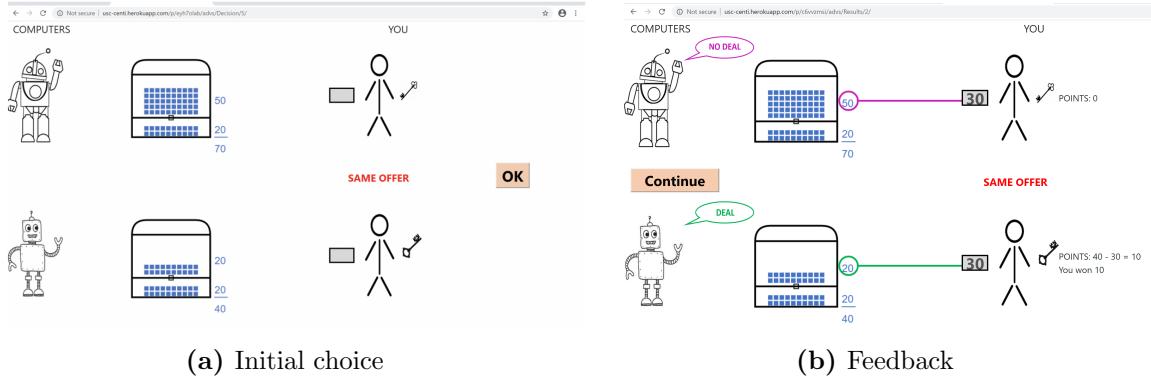

---

<sup>5</sup>We also had the opportunity to conduct the same experiment with two small samples: 8 math teachers at LILA and 11 master students at USC. In Appendix B we report some summary conclusions of these two populations. There are fewer high schoolers in the sample due to some testing constraints but mostly due to a recent expansion of the school that has attracted a larger cohort of middle schoolers.

<sup>6</sup>Also, there is less mobility to and from LILA than in most US schools since mastering the french language is a necessary condition for admittance and a main reason for staying at the school.

Laboratory (LABEL) in the Department of Economics at USC. Procedures were *identical* in both cases. The experiment was programmed in ‘oTree’ (Chen et al., 2016a) and implemented on touchscreen Surface Pro PC tablets through a wireless closed network. Due to space and time constraints, we sometimes ran two sessions simultaneously.

*The Treasure Game.* In developmental studies, it is of paramount importance to provide a simple, graphical interface and a story which is sound, accessible and appealing to a young population. With this goal in mind, we developed the following narrative. Each of two computer robots own a treasure chest. Chests have an upper and a lower compartment. Robots do not have the key for the lower compartment so the value of the chest to them is the amount of points in the upper compartment. You, the participant, own the keys of the lower compartments. This means that the value of the chests to you is the amount of points in both the upper and lower compartments. You can purchase one or both chests. Robots are preprogrammed to accept any offer equal to or greater than the value in the upper compartment of the chest. Your task is to choose which offer to make given one condition: it has to be the same for both robots.<sup>7</sup> Figures 1a and 1b provide screenshots of the game.<sup>8</sup>

**Figure 1:** Screenshots of the Treasure Game

*Basic theory.* Let  $v_L$  and  $v_H$  be the two values for the seller (points in the upper compartments of the chests), with  $0 < v_L < v_H$  and denote by  $v_i \in \{v_L, v_H\}$ . Let  $x (> 0)$  be the extra value for the buyer (points in the lower compartments of the chests which,

<sup>7</sup>Formally, if the participant inputs an offer for one robot, the offer for the other robot gets automatically populated with the same number.

<sup>8</sup>During the design phase, we read the instructions to a small set of students (who obviously did not participate in the experiment) and noticed that some children had a hard time accepting asymmetric valuations. A chest with different compartments and a privately owned key was a natural way to explain it. Using robots instead of humans emphasized the deterministic nature of the decision rule of opponents.

for simplicity, are constrained to be the same in both chests). Under common knowledge of  $(v_L, v_H, x)$ , if the buyer offers a price  $p$  his payoff  $\pi(p)$  is:

$$\pi(p) = \begin{cases} 0 & \text{if } p < v_L \\ (v_L + x - p) & \text{if } v_L \leq p < v_H \\ (v_L + x - p) + (v_H + x - p) & \text{if } v_H \leq p \end{cases}$$

This means that the optimal price  $p^*$  and the corresponding payoff  $\pi(p^*)$  are:

$$p^* = \begin{cases} v_L & \text{if } v_L + x \leq v_H \\ v_H & \text{if } v_L + x \geq v_H \end{cases} \quad \text{and} \quad \pi(p^*) = \begin{cases} x & \text{if } v_L + x \leq v_H \\ x + v_L + x - v_H & \text{if } v_L + x \geq v_H \end{cases}$$

Notice that, while the logic behind the optimal price is identical in our setting than under the standard multiplicative structure, the analytical formulation is simpler. This simplification allows us to screen out computational mistakes and concentrate on cognitive mistakes that are not based on the ability to manipulate quantities. Also, the pre-announced strategy of the robots transforms the game into an individual decision making problem (as pioneered by [CL]), but it still retains many features of a strategic game.<sup>9</sup>

*Timing.* The experiment involved the following six steps. First, we read the instructions. Second, we implemented a computerized, four-question, multiple choice quiz that every participant had to answer correctly before moving on.<sup>10</sup> Third, we moved to the paid part of the experiment. To further facilitate comprehension of the game, we followed [MVN] and started with three (paid) “warm-up” rounds of the Treasure Game, where subjects played against only one robot, and only one chest with values  $v$  and  $x$  in the upper and lower compartments, respectively.<sup>11</sup> This was followed by twelve rounds of the core game with two robots, see Figure 1a.<sup>12</sup> The only difference across rounds were the values in the upper and lower compartments of the chests  $(v_L, v_H, x)$ . Values were chosen in a way that the optimal price  $p^*$  switched every two rounds between  $v_L$  and  $v_H$ . This section was self-paced. After each round, participants received feedback on whether the offers were accepted by the robots (no deal or deal) and the net points accumulated,

---

<sup>9</sup>As emphasized in the surveys by Sutter et al. (2019) and List et al. (2018), most economic experiments with children and adolescents focus on rationality of choices, time preferences, risk preferences and social preferences. There are a few exceptions of games of strategy studies (e.g., Murnighan and Saxon (1998); Harbaugh and Krause (2000); Sher et al. (2014); Czermak et al. (2016); Chen et al. (2016b); Fe et al. (2020); Brocas and Carrillo (2019)).

<sup>10</sup>If a participant missed one or more answers, a warning sign would appear stating “not all answers are correct, please try again”. We provided individual coaching for individuals who struggled with some question (around 10%-15% of our participants).

<sup>11</sup>Our initial idea for the warm-up rounds was to have to robots but allow two different prices. Given the success of the one-robot treatment in [MVN], we decided to follow their design.

<sup>12</sup>Notice that the screen reports not only the values in each compartment but also the total. Again, the goal is to minimize departures from optimality that are due exclusively to computational mistakes.

zero under no deal and value of the chest minus price offered ( $v_i + x - p$ ) under deal, as reflected in Figure 1b. Fourth, there was a two-part, non-incentivized questionnaire. The first part was one round identical to the main game except that we also elicited the participants' confidence in their response.<sup>13</sup> The second part was one round analogous to the main game but framed in the standard probabilistic setting, also with a question regarding the participants' confidence. The goal of this section of the experiment was to obtain a quick, simple (but obviously crude) measure of [MNV]'s power of certainty in our setting.<sup>14</sup> Fifth, we ran a computerized version of the Backwards Digit Span Task (Wechsler, 1949). Participants observed a sequence of digits in their screen and had to report them in reverse order. Digits appeared sequentially for 0.5 seconds with an interval of 0.75 seconds between digits. We started with three digits and increased the sequence by one digit every two trials until we reached eight digits, for a total of twelve trials. Participants would obtain points in a trial only if they reported the entire sequence correctly. The Digit Span Task is a simple behavioral measure of working memory capacity. Working memory refers to the ability to maintain and manipulate information during a cognitive activity (Baddeley and Hitch, 1974) and it is critical to reasoning tasks, in particular tasks that require several reasoning steps and the manipulation of multiple pieces of information (Engle et al., 1999). Since the Treasure Game requires working memory and cognitive processing, we conjectured a positive correlation between performance in the Digit Span Task and optimal choice in the game. This section was also self-paced. Naturally, participants were not allowed to use any external support (such as writing down the numbers as they appear). Sixth and last, we conducted a questionnaire regarding, age, gender, siblings and favorite topic at school. In Appendix A, we present a transcript of instructions, quiz, and two-part questionnaire, as well as a full description of the payoffs used in the 15 rounds of the Treasure Game.

*Payoffs.* Participants accumulated points during the experiment. Points were converted into money paid immediately at the end of the experiment in cash (USC) or with an amazon e-giftcard (LILA, where cash transfers on premises are not allowed). The conversion rate was \$0.02 per point. There was a \$5 show-up fee paid only to USC students to account for differences in marginal value of money and opportunity cost of time. Average earnings were \$12.5 at LILA and \$14.2 + \$5 show-up fee at USC. The experiment never exceeded 50 minutes (one school period) including instructions and payments.

---

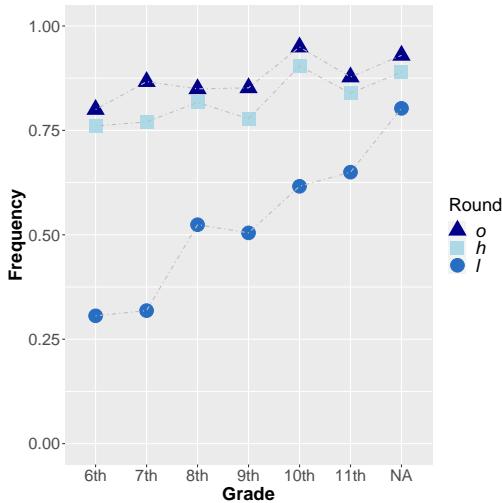

<sup>13</sup>We asked: “Do you think your offer got you the most possible points?” (Yes / Maybe / No).

<sup>14</sup>To be clear, our study *is not* centered around the comparison between the deterministic and probabilistic versions of the Treasure Game, as in [MNV]. Based on previous research on adults, we believed that the deterministic version would be already demanding enough for our population. Our core question is the evolution with age of contingent thinking in its simplest version and the correlates with cognition.

### 3 Results

#### 3.1 Aggregate behavior

We first study aggregate choices in the LILA population and compare it with the control USC group. Figure 2 reports the average fraction of optimal play in each grade. We separate the analysis between the first three warm-up rounds with one computer where the optimal offer is  $v$  ( $o$ -rounds), the six rounds with two computers where the optimal offer is  $v_L$  ( $l$ -rounds) and the six rounds with two computers where the optimal offer is  $v_H$  ( $h$ -rounds). However, remember that  $l$ - and  $h$ -rounds are intertwined in the experiment. Finally, for the rest of the paper, we also count as an optimal choice if the participant offers one token above the optimal number ( $v+1$  in  $o$ ,  $v_L+1$  in  $l$  and  $v_H+1$  in  $h$ ). Indeed, subjects were concerned about the tie-breaking rule. Despite our explanations during the instruction period, it is evident from the answers that some individuals preferred to “play it safe.” With a slight abuse of notation, we call  $v^+ \in \{v, v+1\}$ ,  $v_L^+ \in \{v_L, v_L+1\}$  and  $v_H^+ \in \{v_H, v_H+1\}$ .

**Figure 2:** Optimal play by grade

Our first cut at the data already delivers some interesting conclusions. Optimal choice is very frequent in all school-age grades in  $o$ -rounds and  $h$ -rounds, between 76.1% and 94.9% of the time, with no significant differences between  $o$  and  $h$  in any grade except 7th ( $p = 0.019$ ). There are significant differences across grades between 6th-7th grade and 10th grade in both  $o$  and  $h$ , but they do not survive multiple comparison corrections.

Optimal choice is lower in  $l$ -rounds than in  $h$ -rounds in all school age grades ( $p < 0.01$ )

for 6th to 10th grade and  $p = 0.020$  for 11th grade), and marginally lower in the control population ( $p = 0.048$ ). In  $l$ -rounds, we also observe significant improvement between 6th-7th grade and 10th-11th grade ( $p < 0.005$  after multiple comparison corrections using false discovery rate controlling procedures). Overall, the preliminary results indicate a relatively higher fraction of optimal behavior compared to the previous literature. Not surprisingly, optimal choice is significantly less frequent when it prescribes foregoing the high value item.

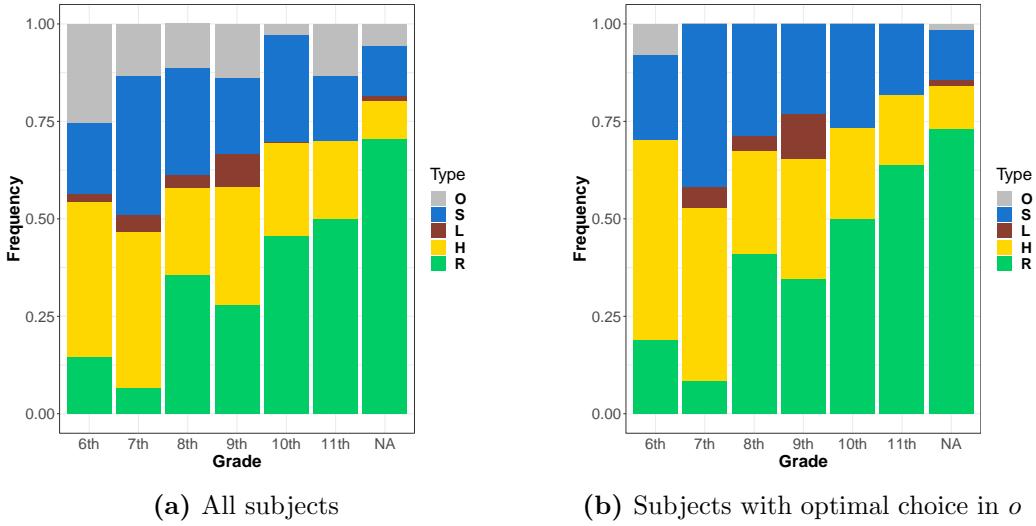

### 3.2 Individual analysis

Although aggregate behavior is instructive, we are more interested in understanding choice at the individual level. To this purpose, we classify individuals as a function of their behavior in  $l$  and  $h$  and consider the following types. *Rational* (**R**) is an individual who always offers the optimal price ( $v_L^+$  in  $l$  and  $v_H^+$  in  $h$ ). *High* (**H**) is an individual who would play optimally if all rounds were  $h$  (always offers  $v_H^+$ ). *Low* (**L**) is an individual who would play optimally if all rounds were  $l$  (always offers  $v_L^+$ ). *Semi-rational* (**S**) is an individual who understands that the only prices that can be optimal are  $v_L^+$  and  $v_H^+$  but is not of one of the types above (offers  $v_L^+$  and  $v_H^+$  in some other proportions). *Other* (**O**) is an individual who offers prices other than  $v_L^+$  or  $v_H^+$ , and has therefore missed the fundamentals of the game. To accommodate some minor deviations, we allow for one deviation both in  $l$ -rounds and in  $h$ -rounds. This means that at least five out of six choices must fall in the corresponding type.<sup>15</sup> Figure 3a reports the proportion of individuals of each type by grade in the entire population (332 participants). Figure 3b reports the same information in the subpopulation of individuals who played correctly all three  $o$ -rounds (76.6% of LILA students and 88.7% of USC students for a total of 263 participants).

Even our youngest school-age participants understand remarkably well the fundamentals of the game. Indeed, only 3.0% (10th grade) to 25.5% (6th grade) of the subjects offer prices other than  $v_L^+$  or  $v_H^+$ . Furthermore, and as highlighted in Figure 3b, of the 41 type-**O** subjects, the vast majority (37) are individuals who did not play correctly the  $o$ -rounds. It means that individuals who understand the basic one-robot problem invariably avoid any price other than  $v_i^+$  in the two-robot problem. The proportion of rational subjects increases with age (differences between 6th-7th and 8th to 11th,  $p < 0.01$  after multiple comparison corrections). Consistent with the findings in section 3.1, a significant fraction of individuals (25.9%) choose  $v_H^+$  in every round (**H**) whereas very few of them (2.7%) choose the more conservative  $v_L^+$  in every round (**L**). Overall, there is a gradual

---

<sup>15</sup>Small changes in the deviations allowed have no significant effects on the results. Those robustness checks are omitted for brevity but available upon request.

**Figure 3:** Types by grade

shift from non-optimal  $v_i^+$  prices (**H** and **S**) to optimal  $v_i^+$  prices (**R**) with age. There are also no significant differences between 11th graders and U.

Among the 73 individuals classified as **S**, we observe all types of deviations: 46.6% play optimally in  $h$  but not in  $l$ , 26.0% play optimally in  $l$  but not in  $h$ , and the rest do not play optimally in either  $h$  or  $l$ . There is also no evidence of learning among these participants (learning is, by construction, only a possibility for **S** and **O** types). Indeed, if we consider only the last 8 rounds of the experiment, only 4 of these subjects are reclassified as **R**. The absence of learning is consistent with the original findings in [CL] but contrasts with recent results (Ali et al., 2019). We find it surprising, especially in our deterministic environment. Indeed, since we provide feedback against both sellers, no counterfactual thinking is necessary, and offering  $v_H^+$  in an  $l$ -round translates into a negative payoff against one robot.<sup>16</sup> One possible explanation is that all learning in the experiment occurs during  $o$ -rounds.

We did not find discernible patterns of play among the 41 participants classified as **O**: 1 subject offers prices between  $v_L^+$  and  $v_H^+$  in 8 rounds, 2 subjects offer prices above  $v_H^+$  in all 12 rounds while the remaining 38 subjects offer prices in the whole spectrum. Overall, these individuals appear lost, with no consistency of behavior and no sign of improvement after feedback.

Finally, it is informative to contrast our results with [MNV]. The exercise should be

<sup>16</sup>No learning is easier to understand when a participant offers  $v_L^+$  in an  $h$ -round since the choice results in an unrealized gain. However, remember that **L** subjects are rare.

taken with a grain of salt, not only because of the widely different populations (school-age and college students vs. MTurk workers), but also due to the significant differences in design and procedures.<sup>17</sup> Since their treatment  $onevalue_{det}$  is closest to our design (and the one where subjects performed best), we use it as the benchmark for comparison. In that treatment, optimal behavior occurs 47.2% of the time, which is similar to our 10th-11th graders (47.6%) and significantly lower than our undergraduates (70.4%,  $p = 0.001$ ). Prices other than  $v_i^+$  occur 26.4% of the time, which is comparable to our 6th graders and higher than all other school-age participants grouped together (11.2%,  $p < 0.001$ ) and also higher than our undergraduates (5.6%,  $p < 0.001$ ). Finally, the simple one firm setting is solved correctly by 62.6% of subjects, which is significantly smaller than our school-age subjects (76.6%,  $p < 0.001$ ) as well as our college students (88.7%,  $p < 0.001$ ). In general, and with the above mentioned important caveat in mind, departures from theory are typically smaller in our control group—and to some extent also in our school-age students—than in the existing literature on adults.

### 3.3 Regression analysis

We perform OLS regressions of individual choices to better understand the determinants of optimal play. Since our main interest is the developmental aspect, we consider only the 261 subjects in the school-age population (LILA).<sup>18</sup> In column (1), we report for each individual the proportion of optimal choices in  $h$ -rounds ( $v_H^+$ ) as a function of the participant's *Age* (in months) at the time of the experiment. In column (2), we add as a control variable the proportion of correct answers in the simple  $o$ -rounds, *correct-o*. In column (3), we also include dummy variables for gender (*Male* = 1), whether the participant has one or more siblings (*Siblings* = 1), and favorite topic at school to account for analytical inclination (*STEM* = 1).<sup>19</sup> Column (4) performs the same regression as (3) but only in the subsample of 200 individuals who answered correctly the three initial  $o$ -rounds, since those participants have presumably understood the fundamentals of the game (naturally, we do not include the variable *correct-o*). In columns (5) to (8) we conduct the same set of regressions but with the data from  $l$ -rounds ( $v_L^+$ ). Finally, in

---

<sup>17</sup>Our in-person, graphical instructions and quiz together with our additive formulation and feedback are likely to facilitate understanding and therefore be conducive to optimal choices. On the other hand, the smaller number of periods and the intertwining of  $l$ - and  $h$ -rounds could presumably make our game more challenging.

<sup>18</sup>We cannot add the USC population since we did not collect their age. Even if we did, we would not want to include them in the regression as it could severely impact the age-trend. We view these subjects as a good control group but not as an extension of the school-age population.

<sup>19</sup>STEM refers to a self-reported preference for either Mathematics or Science/Technology. Consistent with the curriculum of the school, the three other categories offered are Languages, History/Geography and Arts/Music, which we globally refer to as 'Arts & Humanities'.

columns (9) to (12) we merge both sets of observations and include a dummy variable for  $l$ -rounds as well as an interaction term between age and performance in  $l$ -rounds. Results are presented in Table 2.

Consistent with the trends in Figure 2, age has no significant effect in  $h$ -rounds and a very strong effect in  $l$ -rounds, whether we include control variables or not. The combined regressions confirm those findings: performance in  $l$  is much lower than in  $h$ , and behavior improves with age but only in  $l$ -rounds. The improvement is constant, and males perform better than females but only in the more difficult  $l$ -rounds.<sup>20</sup> This is in sharp contrast with our previous research in dominance-solvable games (Brocas and Carrillo, 2019), where females outperformed males and behavior reached a plateau by middle school. Interestingly, a better performance by males is also reported in [MN] on a very different population. We found no effect of siblings or preferred school topic. Finally, performing correctly the simplest  $o$ -rounds is a very strong predictor of optimal behavior in  $h$ - and  $l$ -rounds. This is not overly surprising since only individuals who price accurately against one robot are likely to choose  $v_i^+$  against both.<sup>21</sup>

In order to have a better understanding of the determinants of rational play, we conduct a multinomial logistic regression of the participants' type on their age as well as the previous dummies for gender, siblings, and STEM inclination. The default category in that regression is type **S**. The results reported in Table 3 indicate that the likelihood of being categorized as **R** instead of **S** is positively related to age. It is also more likely when the participant is male and has a preference for STEM. This latter result is reminiscent of Brocas and Carrillo (2019) where we show that strategic performance is higher among students who report an analytical inclination.<sup>22</sup>

## 4 Other analysis

### 4.1 Deterministic vs. stochastic presentation

Remember that, immediately after the paid rounds, we elicited (non-incentivized) behavior in a deterministic and a probabilistic version of the game (see section 2 and Appendix A3). This simple (but obviously imperfect) procedure allows us to obtain a basic measure of the effect of presentation. We selected values in such a way that the optimal price

---

<sup>20</sup>There is no gender difference in the simplest  $o$ -rounds either (regression omitted for brevity).

<sup>21</sup>We performed a robustness check by running additional regressions where *correct-o* is replaced by a dummy variable with value 1 for subjects who play all three  $o$ -rounds correctly. The results are unchanged.

<sup>22</sup>We also created a dummy variable for each possible type (**R**, **H**, **L**, **S**, **O**) and performed independent Probit regressions to explain the probability of being categorized as each of these types on the same independent variables. These regressions confirm that the probability of being categorized as **R** instead of not **R** is correlated with age.

**Table 3:** Multinomial logistic regression of Types

is  $v_L$  in both cases.<sup>23</sup> Figure 4a reports the fraction of participants in each grade who answered correctly both questions (BOTH), only the deterministic (DET), only the probabilistic (PROB) and none of them (NONE). Figure 4b presents those same fractions as a function of the individual’s type in the main experiment.

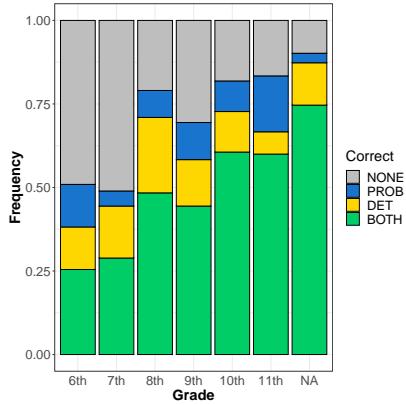

From Figure 4a, we notice that the evolution with age of individuals who respond correctly to both questions follows the same pattern as the evolution of **R** types in Figure 3a: a sustained increase (in this case, from 25% to 75%) with significant differences between 6th-7th and 10th-11th ( $p < 0.030$ ). Less than one in four students answer correctly exactly one question and, in support of [MNV], the correct answer is statistically more frequent with the deterministic presentation than with the probabilistic one (14.5% vs. 8.4%,  $p = 0.020$ ). Figure 4b highlights the tight relationship between choices in the incentivized task and questionnaire: BOTH is highest among **R** followed by **S**. Individuals who always choose  $v_H^+$  (**H**) or prices other than  $v_i^+$  (**O**) rarely answer the questions correctly.<sup>24</sup>

Among subjects with an incorrect response to the deterministic question (PROB and NONE), 80.0% offer  $v_H^+$  in that question and the rest offer prices in the whole spectrum. Among subjects with an incorrect response to the probabilistic question (DET and NONE), 72.9% offer  $v_H^+$  in that question and 9.3% offer  $(v_L^+ + v_H^+)/2$ . Hence, there is a small

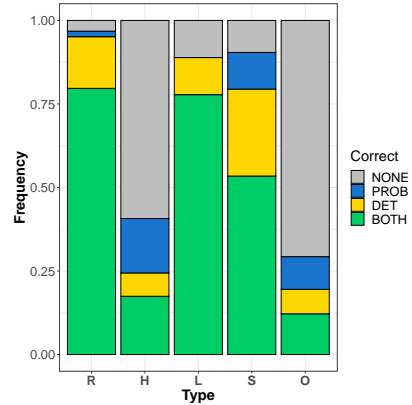

---

<sup>23</sup>We assumed (correctly given the results in section 3) that it was more difficult to play correctly in  $l$ -rounds than in  $h$ -rounds.

<sup>24</sup>Type-**L** individuals also answer the questionnaire correctly. However, there are only 9 subjects. Also, it is possible that they use a heuristic (always offer  $v_L^+$ ) that “coincides” with the optimal choice in our two questions.

(a) Choice by grade

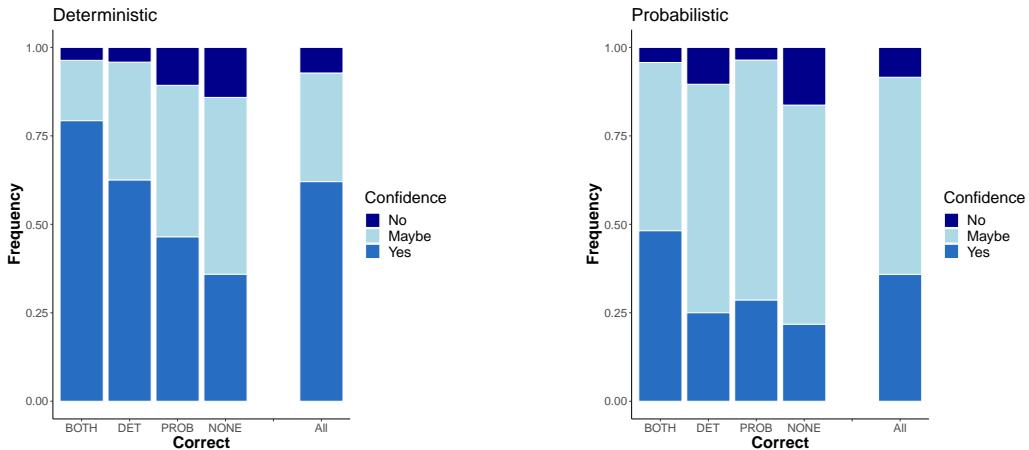

(b) Choice by type

**Figure 4:** Choice in the deterministic and probabilistic questions

but positive ‘‘cursedness’’ effect (offer the average value), which arises only under the probabilistic presentation. As we discuss next, the presentation has some other subtle effects.

In the questionnaire, we also asked our participants to report if they believed they had made the best possible offer (Yes / Maybe / No), in an attempt to elicit the confidence in their answer. Figure 5 reports their confidence as a function of their choice.

**Figure 5:** Confidence in correctness of their choice

Participants are significantly more confident in the correctness of their response under the deterministic presentation (left) than under the probabilistic presentation (right). This

is true not only for individuals who answer both questions correctly (79.3% vs. 48.2%,  $p < 0.001$ ), but also for the others (45.2% vs. 23.8%,  $p < 0.001$ ). Again, it supports the argument in [MNV] that individuals find contingent reasoning more difficult when presented in a probabilistic setting. In our case, the presentation translates into a small difference in choice and a larger difference in confidence.

## 4.2 Backwards Digit Span Task

The Digit Span Task has been frequently used in Psychology and Neuroscience to measure working memory, the fundamental ability to retain and manipulate information for a brief period of time (less than 30 seconds) during a cognitive task.<sup>25</sup> Working memory is recognized as a contributor to fluid intelligence and the Digit Span Task is administered as a specific section of intelligence tests in children, as well as in adults, such as the Wechsler's Intelligence Scale ([Wechsler, 1949](#)). The task has been rarely used by experimental economists, who favor instead other tasks that provide more general assessments of fluid intelligence, most notably different versions of the Raven's IQ test (see e.g., [Brañas-Garza et al. \(2012\)](#); [Gill and Prowse \(2016\)](#); [Proto et al. \(2019\)](#); [Fe et al. \(2020\)](#)). Performances in Raven and Digit Span are often correlated. This is not surprising given that solving the logical puzzles in the Raven's test requires working memory among other abilities. We view both tests as complementary and advocate expanding the use of different measures as a rich way to assess cognitive ability. Perhaps one advantage of the Digit Span Task is its narrower focus on one particular primitive ability, which allows us to determine whether working memory is or is not a contributor in the performance of the decision making task.

Although the original version of this task was verbally administered, recent versions typically use a computer interface. The task exists in two variants: forward-span and backward-span. The backward-span version requires the participant not only to hold the digits longer in their working memory but also to manipulate them because they need to be reordered. It is considered a better measure of working memory capacity ([Oberauer et al., 2000](#)). It has also been shown that the ability to perform well on this additional difficulty of the task can be linked to general intelligence ([Jensen and Figueroa, 1975](#)). Table 4 reports the average performance in each grade by counting the percentage trials that the participant performs correctly.<sup>26</sup>

---

<sup>25</sup>For the reader unfamiliar with the Psychology and Neuroscience literatures, it is worth clarifying that working memory does not relate to the traditional definition of memory, that is, the ability to recall events from the past. Instead, it is a cognitive processing ability that involves very different areas of the brain.

<sup>26</sup>It is frequent in Psychology to assess performance by stopping the first time a report is incorrect. Our method is more permissive with mistakes. It also adapts better to our task since all trials are incentivized and performance feedback is obtained only at the end of the experiment. If we adopt the standard methodology, the average span is 3.08 for our school age students and 4.16 for our undergraduates. These

Grade	LILA						USC
	6th	7th	8th	9th	10th	11th	
Correct	40.2	45.3	45.6	47.0	52.5	54.8	70.1

**Table 4:** Average percentage of correct trials in Digit Span Task by grade

The number of correct trials in the school-age population is significantly lower than in the control undergraduate group. While performance in the Digit Span Task is valuable in itself, we are more interested in correlating it with performance in the task. Optimal performance in the Treasure Game necessitates the combination of several abilities. First, the individual must realize that offers other than  $v^+$  (in  $o$ ) and  $v_i^+$  (in  $h$  and  $l$ ) are necessarily suboptimal. Then, the subject must be able to determine which offer among  $v_L^+$  and  $v_H^+$  maximizes payoffs depending on the round. To find out which abilities correlate with working memory ability, we perform OLS regressions at the individual level, where the dependent variable is performance in the Digit Span Task. We consider only school-age participants and use as regressors *Age* in months and the same control variables as before (gender, siblings and favorite topic). We also include a combination of performance in  $o$  and  $l$  (column (3)) or performance in  $h$  and  $l$  (column (4)) to measure the contribution of the different cognitive abilities. Notice that we do not include performance in  $o$  and  $h$  in the same regressions since we know from Table 2 that these two measures are highly colinear. The results are reported in Table 5.

Confirming the existing results in the literature (Gathercole et al., 2004), performance in the Digit Span Task increases significantly with age. Individuals with an inclination for analytical topics (self-reported preference for STEM) perform better. Most notably, there is a positive association between optimal choice and working memory. This is particularly visible for choice in the simpler  $o$ - and  $h$ -rounds, which both very significantly predict performance in the Digit Span Task. The positive but statistically less significant effect of performance in  $l$ -rounds suggest that working memory also supports, although to a lesser extent, the more subtle step that consists in discriminating between  $v_L^+$  and  $v_H^+$ .

Given that the (potential) link between working memory and contingent reasoning is correlational, our next set of regressions uses performance in the Digit Span Task as an explanatory variable of the participant's type in the Treasure Game. Participants classified as **O** have the lowest scores (4.35) while those classified as **R** have the highest scores (6.33). The score of **O** types is significantly lower than that of **H**, **S** and **R** and the differences between **H** and **R** are also significant ( $p < 0.04$  after correcting for multiple comparisons).

---

numbers are comparable to existing studies reporting averages between 3 and 4 in children and adolescents (Hale et al., 2002) and between 4 and 5 in adults (Gignac, 2015).

(standard errors in parenthesis)

\* p < 0.05; \*\* p < 0.01; \*\*\* p < 0.001

**Table 5:** OLS regressions of performance in the Digit Span Task

Naturally, these effects are partly driven by age differences across types. To control for age effects, we ran a multinomial logistic regression of the type of each participant similar to the one reported in Table 3, except that we grouped types **L**, **H** and **S** in one category (the new default), and we added the performance in the Digit Span Task as an independent variable (*DigitSpan*).

Table 6 reinforces the results from Table 5. After controlling for age and other individual characteristics, we still observe that performance in the working memory task is lower by **O** subjects and higher by **R** subjects. The result indicates that a better working memory helps performance significantly, especially in the simpler rounds. At the same time, it is not sufficient for optimal behavior, and other cognitive processes are also involved in the calculations required by contingent reasoning. This finding has implications for the study of complex games that require a priori sophisticated logical skills.

## 5 Conclusion

Our study shows that performance in choices involving contingent reasoning is critically linked to the complexity of the task. The fundamentals are grasped by our youngest participants but the ability to solve the most subtle aspects develops gradually with age. It is not facilitated by repeated exposure or feedback. A higher score in working memory is positively associated with performance.

The study provides a foundational approach to the development of contingent reasoning. It brings further evidence that age plays a critical role in the development of strategic thinking. Previous studies have shown that children develop inductive logic between the ages of 8 and 12 (Feeney and Heit, 2007) and the ability to perform hypothetical and counterfactual thinking between the ages of 11 and 14 (Piaget, 1972; Rafetseder et al., 2013). Observing that conditional reasoning abilities develop during that time period and beyond is consistent with that evidence. However, our recent studies have reported a steep development throughout elementary school (ages 6 to 11) and a lack of improvement past that period in backward induction games (Brocas and Carrillo, 2019). Stagnation occurs even though the ability is not necessarily mastered at that age, indicating that children may have reached a cognitive bound. The significant improvements in the present game during middle and high school contrast with that evidence, and implies that developmental

trends and cognitive boundaries are game-specific. It also suggests that age effects may extend beyond adolescence, from young adulthood and all the way to old adulthood, an issue that has been under-studied in the literature.

Despite the caveats noted, the results obtained here are consistent with [MNV]. Our oldest school-age participants and undergraduates perform better than in the traditional ‘acquire-a-company’ game. There is no evidence of cursedness, indicating that this behavioral feature may be tightly linked to the probabilistic presentation. The increased performance of our subjects relative to [MNV] is likely due to our higher control level and more educated population (lab-in-the field experiment with a homogenous population of private school high schoolers and college undergraduates vs. MTurk workers) as well as the simpler, graphical design. Finally, the responses of participants support the idea that uncertainty is a main obstacle for optimal performance.

Our data reveals an unexpected gender difference. Conditional reasoning is a logical ability and there is no evidence of a specific gender bias in the literature studying logic, cognition and IQ. At best, results are mixed and differences are typically small ([Lynn and Irwing, 2004](#); [Reynolds et al., 2008](#)). Still, gender differences have been observed in game theoretic settings involving steps of reasoning in adults ([Cubel and Sanchez-Pages, 2017](#)) and children ([Brocas and Carrillo, 2019](#)). Depending on games and treatments, males or females may perform better. It is, however, intriguing and worthy of further investigation that the same gender effect is present in our study and in [MNV], despite the large differences in the populations studied.

Participants with a preference for science tend to have a higher performance in both the working memory and the contingent reasoning tasks. This is consistent with the literature showing that working memory is associated with academic achievement in science-related topics ([Alloway and Alloway, 2010](#); [Swanson, 2011](#)) and with studies showing a relationship between high cognition and performance in games ([Brañas-Garza et al., 2012](#); [Gill and Prowse, 2016](#); [Proto et al., 2019](#); [Fe et al., 2020](#)). It is also in line with our earlier research where we showed that a preference for science is associated with better performance and higher payoffs ([Brocas and Carrillo, 2019](#)). The present study also suggests that a highly developed working memory capacity is a necessary condition to solve complex reasoning tasks, although it may not be sufficient.

Our results also illustrate the methodological value of studying basic cognitive abilities and assessing their relationship with performance in games. There is converging evidence that cognition and decision-making go hand-in-hand. Cognitive development and age-related changes in decision-making cannot be dissociated. Basic cognitive functions refer to simple processes such as working memory (the ability to manipulate pieces of information) and inhibitory control (the ability to reject distracting or irrelevant features). These

functions are recruited to complete simple cognitive tasks (such as number manipulation and mental rotation of objects) but also complex cognitive tasks (such as contingent reasoning and deductive logic). Decision-making is a form of complex cognitive activity, which often combines several kinds of logic to be carried efficiently. Therefore, non-compliance to central predictions of theory may be traced to several fundamentally different causes. Testing cognitive abilities independently allows us to identify which feature of the decision poses a problem.<sup>27</sup> In our case, low performance in working memory accounts for a large part of suboptimal choices. The rest is explained by failure of contingent reasoning and it is traced to a limited logical reasoning capacity. This suggests that, in general, it may be incorrect to associate non-equilibrium play exclusively to limitations in higher-order logical abilities. We believe that a better understanding of the relative contribution of the different cognitive abilities (e.g., basic working memory vs. complex deductive logic) has long range implications for the design of behavioral models. Also, while studying the relationship between basic cognitive abilities and decision-making is particularly interesting in children, it should also be enlightening in studies with adults.

The results have vast implications for policy intervention. Indeed, contingent reasoning is ubiquitous in strategic interactions. Developing this ability is critical to assess the motivations of others and to anticipate their reactions to our choices. A person who does not apply contingent reasoning properly can be taken advantage of by people who misrepresent their intentions. This is particularly problematic in the case of adolescents. Indeed, they are often targeted by cyber threats and scams. Drug abuse, criminality and other risky choices are also heavily influenced by others (Steinberg, 2008). Evidence links these behaviors to biological factors, such as hormonal changes that occur with the onset of puberty but also brain development of regions associated with affective reactivity and emotion regulation ability (Nelson et al., 2005). Many of these regions are located in the prefrontal cortex, the area that matures last and is broadly involved in logical abilities. Taken together, this evidence suggests that suboptimal risky choices in adolescents is often the result of a limited ability to logically infer the intentions of others. Our results, which demonstrate in a controlled laboratory setting that contingent reasoning is developing during adolescence, support these biological findings. They indicate that intervention is needed to protect teens in situations they are not equipped to handle. This may include the regulation of the internet and social media interactions, and the increase of professional counseling in schools.

---

<sup>27</sup>There exists a large variety of tasks that assess cognitive functions. Some are specific, such as the Digit Span task and its homologue spatial form the Corsi task. Their objective is to diagnose a well-defined ability. Others are general, such as IQ tests. Their objective is to provide a score regarding the overall cognitive level of a person.

## Appendix A. Experimental details

### A1. Instructions - LILA

Today, we are going to play a few games with you. In those games, you will earn points that will be converted into money and placed in your virtual wallet. Each point is worth 2 cents. At the end of the session, we will send to your LILA email address an Amazon gift card with the money you earned. You will start with 300 points, so \$6.00.

#### Treasure Game

In this game you will play against robots. Robots are computer programs that play in a predetermined way. We are going to tell you how. Here is an example. This is the computer you are playing with [point] and this is you [point] (see Figure 6 for the slides).

[ SLIDE 1: screen with one robot ]

The computer owns a treasure box. The box has two compartments, an upper compartment and a lower compartment. There are points in each compartment [point]. However, the computer does not have the key of the lower compartment and cannot access the points placed there. So, even though the computer knows how many points there are in the lower compartment, the box for the computer is worth only the number of points in the top compartment.

Now, you do have the key of the lower compartment. So, if you buy the treasure box, you will be able to access it. This means that the box is worth to you the points in the upper and lower compartments.

To buy a box, you need to make an offer to the computer, and the offer has to be accepted. Remember that, for the computer, the box is worth only the number of points in the top compartment. If the offer it receives is equal or above that number, it will accept the deal. Otherwise, there will be no deal. The computer is programmed, so this is an automatic rule.

Each time you make an offer, you will know if the trade occurs and how much money you win or lose. Let's look at what can happen.

[ SLIDE 2: screen with one robot and DEAL ]

If you offer 60 (and this is just an example), the computer will accept it and you will be notified that there is a deal. You will also learn how many points you earned. In this case,  $70 - 60 = 10$  points.

[ SLIDE 3: screen with one robot and NO DEAL ]

But, if you offer 40 (and, again, this is just an example), the computer will not accept it and you will be notified that the there is no deal. In that case, you will earn 0. To sum up, if your offer is not accepted, you get 0. If your offer is accepted, you accumulate points on your wallet.

Now, there are two types of trading games. At the beginning, you will play with one computer, as we have just described. After a few rounds, you will play with two computers. In that case, you will see a screen like this.

[ SLIDE 4: screen with two robots ]

This is you and these are the two computers you are playing with. What is important to realize is that you have to make **the same offer** to both computers. Each computer sees the offer

and decides whether to accept the deal or not. As before, each computer accepts your offer if it is equal or greater to the number of points in the upper compartment. Therefore, it may be that no computer accepts your offer, one computer accepts your offer and the other doesn't or both computers accept your offer. This also means that you may win points with both computers, or you may lose with some computer. If this happens, don't worry. The points we give you in advance will cover your losses. Finally, your offer can never exceed the total value of the most valuable box. In this example, you cannot offer more than 70.

Practically speaking, you need to enter your offer in one cell and the other will automatically be populated. You are going to play several rounds. Each time, the boxes will have different values. Is that clear?

Before playing, you will answer a short quiz. This is not a test. We are just trying to make sure you have understood the rules because it is important to understand the rules when you play a game. All the questions in the quiz refer to this screen.

[ SLIDE 5: screenshot for quiz ]

[Launch quiz] - [When quiz is done] OK, now we will launch the game. You will be playing several times [Launch game]

The game is over, but we would like you to answer two questions about the game. Read carefully. In the first question, you will see a screenshot like the one in the game you have been playing. In the second question, you will see a screenshot slightly different. The rules are the same as before except that you are playing against one of the two computers, but you do not know which one (each of them is equally likely) [Launch questions]

### **Digit memory game**

In this game, you will see digits, one at a time, on your screen. Each digit will appear for half a second. Then, a new digit will appear after a little bit less than a second. You need to pay attention to the digits and the order in which they are shown because you will have to report them in the reverse order and press OK. Here is an example:

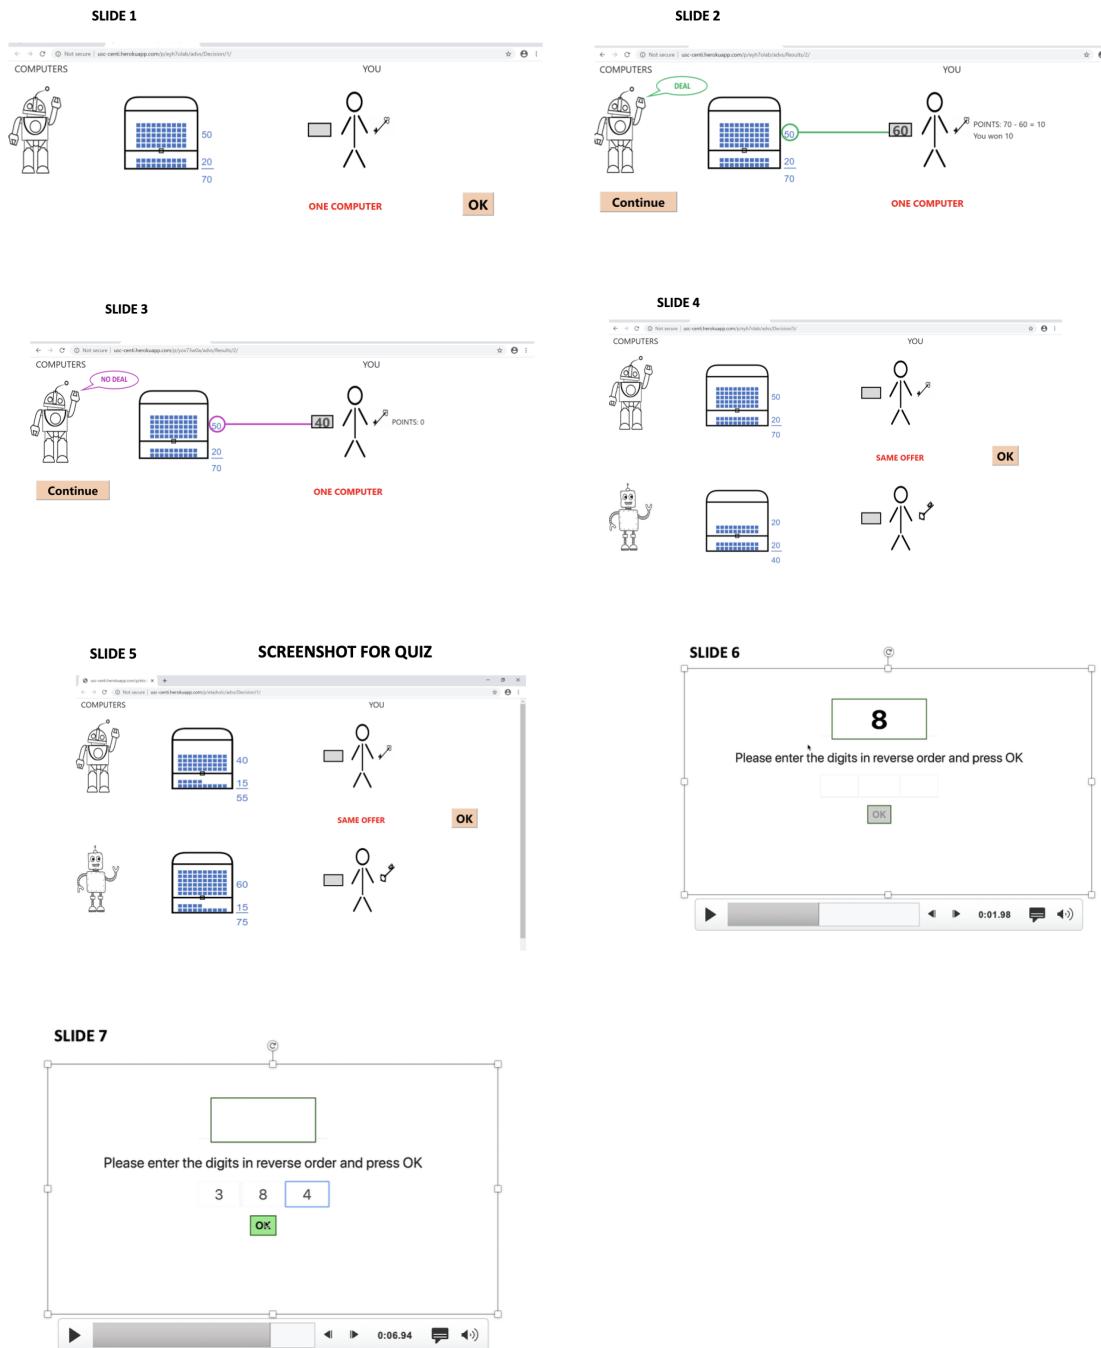

[ SLIDE 6: launch video 1 ]

What were the digits? 4 - 8 - 3. Good, so you need to enter them in reverse order: 3 - 8 - 4, and press OK as in the following video.

[ SLIDE 7: launch video 2 ]

You will start with 3 digits and keep increasing until you get to 8 digits. Each time you enter the correct answer, you will earn 20 points and each time you don't enter the correct answer, you will get 0 points, so pay attention! As in the video, the cursor will be automatically set in the left box. Once you input a digit, you will not be able to change it, and the cursor will automatically move to the next box. When you are done, press OK to move to the next set of numbers. Any questions? Please be very quiet during this game [Launch game]

We are done. You will now see the number of points you got in the Treasure game and in the Digit Memory game. You don't need to memorize them. Press OK and fill the questionnaire while we prepare your payment [Launch final questionnaire].

**Figure 6:** Slides used for the instructions

## A2. Quiz

[Questions refer to the screenshot projected in SLIDE 5. Correct answers marked in **bold**].

Suppose you observe this screen, answers the following questions.

1. How many offers can you make?
  - a. **You have to make the same offer to both computers**
  - b. You can make different offers to each computer
  - c. It doesn't say
2. Suppose you offer 65 to each computer. What happens?
  - a. No Deal with top computer and No Deal with bottom computer
  - b. No Deal with top computer and Deal with bottom computer
  - c. Deal with top computer and No Deal with bottom computer
  - d. Deal with top computer and Deal with bottom computer**
3. Suppose you offer 50 to each computer. How many points do you get in your relationship with the top computer (for this exercise do not count what happens with the bottom computer)
  - a. **There is a deal and you win 5 points**
  - b. There is a deal and you win 10 points
  - c. There is a deal and you lose 5 points
  - d. There is no deal so you get 0 points
4. Suppose you offer 50 to each computer. How many points do you get in your relationship with the bottom computer (for this exercise do not count what happens with the top computer)
  - a. There is a deal and you win 5 points
  - b. There is a deal and you win 10 points
  - c. There is a deal and you lose 5 points
  - d. There is no deal so you get 0 points**

## A3. Two-part, non-incentivized questionnaire

Advert (Treatment 1) session 1easyc

https://user-centr.helsinki.fi/15nowBodyDecisions/

COMPUTERS YOU

SAME OFFER OK

Look at this screenshot, it is the same problem you already solved. You need to make **the same offer** to both computers.

Enter your offer:

Do you think your offer got you the most possible points?

Yes  
 Maybe  
 No

OK

Advert (Treatment 1) session 1easyc

https://user-centr.helsinki.fi/15nowBodyDecisions/

COMPUTERS YOU

TOP OR BOTTOM OK

Look at this screenshot. Now you are matched **either with the top computer or the bottom computer**. but you do not know which one of them. There is an equal chance it is either of them. However, you have to make your offer before knowing with which computer you are matched.

Enter your offer:

Do you think your offer got you the most possible points?

Yes  
 Maybe  
 No

OK

#### A4. Payoff combinations in the treasure game

Table 7 reports the payoffs in each chest for each of the 15 rounds. Values in **bold** reflect the optimal offer in that round.

Round		1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Chest 1	upper	<b>45</b>	<b>15</b>	<b>30</b>	20	<b>40</b>	60	40	<b>25</b>	<b>50</b>	<b>30</b>	45	<b>40</b>	20	30	<b>30</b>
	lower	10	20	15	10	15	20	15	15	20	10	15	15	20	15	8
Chest 2	upper	—	—	—	<b>25</b>	30	<b>30</b>	<b>15</b>	15	40	45	<b>20</b>	30	<b>35</b>	<b>10</b>	40
	lower	—	—	—	10	15	20	15	15	20	10	15	15	20	15	8

**Table 7:** Payoffs by compartment and chest

#### Appendix B. Summary of behavior in other populations

Table 8 provides a descriptive summary of the behavior by the 8 math teachers at LILA (Teachers) and the 11 Master students at USC (Masters).

	Optimal play			Type				
	<i>o</i> -round	<i>h</i> -round	<i>l</i> -round	<b>R</b>	<b>H</b>	<b>L</b>	<b>S</b>	<b>O</b>
				0.25	0.25	0.00	0.50	0.00
Teachers	1	0.9	0.58					
Masters	0.79	0.76	0.68	0.55	0.18	0.09	0.09	0.09

	Correct question				Confidence Det.			Confidence Prob.		
	BOTH	DET	PROB	NONE	Yes	Maybe	No	Yes	Maybe	No
					0.75	0.125	0.00	0.125	0.62	0.38
Teachers	0.75	0.125	0.00	0.125						
Masters	0.73	0.00	0.00	0.27						
					0.91	0.09	0.00			

**Table 8:** Summary statistics of behavior by Teachers (LILA) and Masters (USC)

The samples are extremely small to make meaningful inferences. Also, these two populations are relatively heterogenous (in particular, USC master students come from very different intellectual backgrounds). The results, however, indicate that Teachers and Masters do not behave very differently from 11th grades and undergraduates.
